Dex-Net 3.0: Computing Robust Robot Suction Grasp Targets in Point Clouds using a New Analytic Model and Deep Learning
Jeffrey Mahler\textsuperscript{1}, Matthew Matl\textsuperscript{1}, Xinyu Liu\textsuperscript{1}, Albert Li\textsuperscript{1}, David Gealy\textsuperscript{1}, Ken Goldberg\textsuperscript{1,2}

Abstract—Suction-based end effectors are widely used in industry and are often preferred over parallel-jaw and multifinger grippers due to their ability to lift objects with a single point of contact. This ability simplifies planning, and hand-coded heuristics such as targeting planar surfaces are often used to select suction grasps based on point cloud data. In this paper, we propose a compliant suction contact model that computes the quality of the seal between the suction cup and target object and determines whether or not the suction grasp can resist an external wrench (e.g. gravity) on the object. To evaluate a grasp, we measure robustness to perturbations in end-effector and object pose, material properties, and external wrenches. We use this model to generate Dex-Net 3.0, a dataset of 2.8 million point clouds, suction grasps, and grasp robustness labels computed with 1,500 3D object models and we train a Grasp Quality Convolutional Neural Network (GQ-CNN) on this dataset to classify suction grasp robustness from point clouds. We evaluate the resulting system in 375 physical trials on an ABB YuMi fitted with a pneumatic suction gripper. When the object shape, pose, and mass properties are known, the model achieves 99\% precision on a dataset of objects with Adversarial geometry such as sharply curved surfaces. Furthermore, a GQ-CNN-based policy trained on Dex-Net 3.0 achieves 99\% and 97\% precision respectively on a dataset of Basic and Typical objects. Code, datasets, and supplemental material can be found at http://berkeleyautomation.github.io/dex-net.

I. INTRODUCTION

Suction grasping is a widely-used method for pick-and-place tasks in industry and warehouse order fulfillment. As shown in the Amazon Picking Challenge, suction has an advantage over parallel-jaw or multifinger grasping due to its ability to reach into narrow spaces and pick up objects with a single point of contact. However, while a substantial body of research exists on parallel-jaw and multifinger grasp planning [3], comparatively little research exists on planning suction grasps.

While grasp planning searches for gripper configurations that maximize a quality metric derived from mechanical wrench space analysis [25], human labels [29], or self-supervised labels [20], suction grasps are often planned directly on point clouds using heuristics such as grasping near the object centroid [11] or targeting planar surfaces [6], [4]. These heuristics work well for prismatic objects such as boxes and cylinders but may fail on objects with complex geometry. Some analytic models of suction cups exist, but they typically assume that a vacuum seal has already been formed and that the state (e.g. shape and pose) of the object is perfectly known [2], [17], [24]. In practice a robot may need to form seals on non-planar surfaces while being robust to external wrenches (e.g. gravity and disturbances), sensor noise, control imprecision, and calibration errors, which are significant factors when planning grasps from point clouds.

We propose a novel compliant suction contact model for rigid, non-porous objects that consists of two components: (1) a test for whether a seal can be formed between a suction cup and a target object and (2) an analysis of the ability of the suction contact to resist external wrenches. We use the model to evaluate grasp robustness by evaluating seal formation and wrench resistance under perturbations in object pose, suction tip pose, material properties, and disturbing wrenches using Monte-Carlo sampling similar to that in the Dexterity Network (Dex-Net) 1.0 [23].

This paper makes five contributions:

1) A compliant suction contact model that measures seal formation using a quasi-static spring system and measures the ability to resist external wrenches (e.g. gravity) using a contact wrench basis derived from the ring of contact between the cup and object surface.

2) Robust wrench resistance: a robust version of the above model under random disturbing wrenches and...
perturbations in object pose, gripper pose, and friction.

3) Dex-Net 3.0, a dataset of 2.8 million synthetic point clouds annotated with suction grasps and grasp robustness labels generated by analyzing robust wrench resistance for approximately 375k grasps across 1,500 object models.

4) Experiments characterizing the precision of robust wrench resistance both with and without knowledge of the target object’s shape and pose.

5) A taxonomy of object shapes for robot grasping experiments that differentiates 3 classes of objects (Basic, Typical, and Adversarial).

We perform physical experiments using an ABB YuMi robot with a silicone suction cup tip to compare the precision of a GQ-CNN-based grasping policy trained on Dex-Net 3.0 against several heuristics such as targeting planar surfaces, and we find that our method achieves 99% and 97% average precision on the Basic and Typical objects, respectively.

II. RELATED WORK

End-effectors based on suction are widely used in industrial applications such as warehouse order fulfillment, handling limp materials such as fabric [17], and robot applications such as the Amazon Picking Challenge [4], underwater manipulation [31], or wall climbing [2]. Our method builds on models of deformable materials, analyses of the wrenches that suction cups can exert, and data-driven grasp planning.

A. Suction Models

Several models for the deformation of stiff rubber-like materials exist in the literature. Provot et al. [27] modeled sheets of stiff cloth and rubber using a spring-mass system with several types of springs. Hosseini et al. [1] provided a survey of more modern constitutive models of rubber that are often used in Finite Element Analysis (FEA) packages for more realistic physics simulations. In order to rapidly evaluate whether a suction cup can form a seal against an object’s surface, we model the cup as a quasi-static spring system with a topology similar to the one in [27] and estimate the deformation energy required to maintain a seal.

In addition, several models have been developed to check for static equilibrium assuming a seal between the suction cup and the object’s surface. Most models consider the suction cup to be a rigid object and model forces into the object along the surface normal, tangential forces due to surface friction, and pulling forces due to suction [17], [31], [33]. Bahr et al. [2] augmented this model with the ability of to resist moments about the center of suction to determine the amount of vacuum pressure necessary to keep a climbing robot attached to a vertical wall. Mantriota [24] modeled torsional friction due to a contact area between the cup and object similar to the soft finger contact model used in grasping [14]. Our model extends these methods by combining models of torsional friction [24] and contact moments [2] in a compliant ring contact model.

B. Grasp Planning

The goal of grasp planning is to select a configuration for an end-effector that enables a robot to perform a task via contact with an object while resisting external perturbations [3], [30], which can be arbitrary [8] or task-specific [18], [21]. A common approach is to select a configuration that maximizes a quality metric (or reward) based on wrench space analysis [25], robustness to perturbations [34], or a model learned from human labels [29] or self-supervision [26].

Several similar metrics exist for evaluating suction grasps. One common approach is to evaluate whether or not a set of suction cups can lift an object by applying an upwards force [17], [31], [32], [33]. Domae et al. [6] developed a geometric model to evaluate suction success by convolving target locations in images with a desired suction contact template to assess planarity. In addition, heuristics for planning suction grasps from point clouds have been used extensively in the Amazon Picking Challenge. In 2015, Team RBO [7] won by pushing objects from the top or side until suction was achieved using a vacuum with high air flow, and Team MIT [36] came in second place using a strategy that positioned the suction cup directly above the centroid of objects with flat surfaces. In 2016, Team Delft [11] won the challenge using a suction planning strategy that selected the closest point on the object surface to the object centroid and approached the point along the inward surface normal. In this work, we present a novel metric that evaluates whether a suction cup can resist external wrenches given a target point on a 3D model, and we estimate grasp robustness via Monte-Carlo sampling of wrench resistance over perturbations in poses, material properties, and disturbing wrenches.

This paper also extends empirical, data-driven approaches to grasp planning based on images and point clouds [3]. A popular approach is to use human labels of graspable regions in RGB-D images [19] or point clouds [5], [15] to learn a grasp detector with computer vision techniques. As labeling may be tedious for humans, an alternative is to automatically collect training data from a physical robot and to train Convolutional Neural Network (CNN) to predict grasp success [20], [26]. To reduce the time-cost of data collection, recent research has proposed to generate labels in simulation using physical models of contact [13], [15]. Mahler et al. [22] demonstrated that a GQ-CNN trained on Dex-Net 2.0, a dataset of 6.7 million point clouds, grasps, and quality labels computed with robust quasi-static analysis, could be used to successfully plan grasps across a wide variety of objects with 99% precision. In this paper, we use a similar approach to generate a dataset of point clouds, grasps, and robustness labels for a suction-based end-effector.

III. PROBLEM STATEMENT

Given a point cloud from a depth camera, our goal is to find a robust suction grasp (target point and approach direction) for a robot to lift and transport a singulated object from a planar worksurface to a receptacle. We solve for the suction grasp that maximizes the probability that the robot can hold the object under perturbations due to sensor noise.
A. Assumptions

Our stochastic model makes the following assumptions:

1) Quasi-static physics (e.g., inertial terms are negligible) with Coulomb friction.
2) Objects are rigid and made of non-porous material.
3) Each object is singulated on a planar worksurface in a stable resting pose [9].
4) A single overhead depth sensor oriented orthogonally to the worksurface with known intrinsics, position, and orientation relative to the robot.
5) A vacuum-based end-effector with known geometry and a single disc-shaped suction cup made of linear-elastic material.

B. Definitions

A robot observes a single-view point cloud or depth image, \( y \), containing a singulated object. The goal is to find the most robust suction grasp \( u \) that enables the robot to lift an object and transport it to a receptacle, where grasps are parametrized by a target point \( p \in \mathbb{R}^3 \) and an approach direction \( v \in S^2 \). Success is measured with a binary grasp quality function \( S \), where \( S = 1 \) if the grasp \( u \) successfully transports the object, and \( S = 0 \) otherwise.

The robot may not be able to predict the success of suction grasps exactly from point clouds for several reasons. First, the success metric depends on a latent state \( x \) describing the object’s geometric, inertial, and material properties \( O \) and the pose of the object relative to the camera, \( T_o \), but the robot does not know the true state due to: (a) noise in the depth image and (b) occlusions due to the single viewpoint. Second, the robot may not have perfect knowledge of external wrenches (forces and torques) on the object due to gravity or external disturbances.

This probabilistic relationship is described by an environment consisting of a grasp success distribution modeling \( P(S | u, x) \), the ability of a grasp to resist random disturbing wrenches, and an observation model \( P(y | x) \). This model induces a probability of success for each grasp conditioned on the robot’s observation:

Definition 1: The robustness of a grasp \( u \) given a point cloud \( y \) with respect to an environment is the probability of grasp success under uncertainty in sensing, control, and disturbing wrenches: \( Q(u, y) = \mathbb{P}(S | u, y) \).

Our environment model is described in Section V and further details are given in the supplemental file.

C. Objective

Our goal is to find a grasp that maximizes robustness given a point cloud, \( \pi^*(y) = \arg\max_{u \in \mathcal{C}} Q(u, y) \), where \( \mathcal{C} \) specifies constraints on the set of available grasps, such as collisions or kinematic feasibility. However, in practice the robot does not have an explicit representation of the robustness function \( Q \) but has the ability to sample from the stochastic environment. As inferring the state over a large number of possible objects may be challenging, we approximate \( \pi^* \) by training a deep Grasp Quality Convolutional Neural Network (GQ-CNN) \( Q_{\theta}(u, y) \) on samples of success labels, point clouds, and suction grasps from our model by minimizing the cross-entropy loss \( \mathcal{L} \):

\[
\min_{\theta \in \Theta} \sum_{i=1}^{N} \mathcal{L}(S_i, Q_{\theta}(u_{i}, y_{i}))
\] (III.1)

Learning \( Q \) rather than directly learning \( \pi^* \) allows us to enforce task-specific constraints without having to update the learned model. Given optimized GQ-CNN weights \( \theta \), we execute the deep robust grasping policy \( \pi_{\theta}(y) = \arg\max_{u \in \mathcal{C}} Q_{\theta}(u, y) \).

IV. COMPLIANT SUCTION CONTACT MODEL

To evaluate grasp success, we develop a novel quasi-static spring model of the suction cup material and a model of contact wrenches that can be applied through a ring of contact between the object and suction cup perimeter. Our success metric evaluates whether:

1) A seal is formed between the perimeter of the suction cup and the object surface.
2) Given a seal, the suction cup is able to resist an external wrench on the object due to gravity and disturbances.

A. Seal Formation

A suction cup lifts objects with an inwards force due to an air pressure differential induced across the membrane of the cup by a vacuum generator. If a gap exists between the perimeter of the cup and the object, then air flowing into the gap may reduce the differential and cause the grasp to fail. Therefore, forming a tight seal between the cup and the target object is crucial for grasp success.

To determine when seal formation is possible, we model the suction cup as a spring system \( C \) parameterized by real numbers \( (n, r, h) \). Rather than performing a computationally expensive dynamic simulation with a spring-mass model to
determine when seal formation is feasible, we make simplifying assumptions to evaluate seal formation geometrically. Specifically, we compute a configuration of $C$ that achieves a seal by projecting $C$ onto the surface of $M$ and evaluate the feasibility of that configuration under quasi-static conditions as a proxy for the dynamic feasibility of seal formation.

In our model, $C$ has two types of springs – structural springs that represent the physical structure of the suction cup and flexion springs that do not correspond to physical structures but instead are used to resist bending along the cup’s surface. Dynamic spring-mass systems with similar structures have been used in prior work to model stiff sheets of rubber [27]. The undeformed structural springs of $C$ form a right pyramid with height $h$ and with a base that is a regular $n$-gon with circumradius $r$ (see Fig. 2). Let $V = \{v_1, v_2, \ldots, v_n, a\}$ be the set of vertices of the undeformed right pyramid, where each $v_i$ is a base vertex and $a$ is the pyramid’s apex. We define the model’s set of springs as follows:

- **Perimeter (Structural) Springs** – Springs linking vertex $v_i$ to vertex $v_{i+1}$, $\forall i \in \{1, \ldots, n\}$.
- **Cone (Structural) Springs** – Springs linking vertex $v_i$ to vertex $a$, $\forall i \in \{1, \ldots, n\}$.
- **Flexion Springs** – Springs linking vertex $v_i$ to vertex $v_{i+2}$, $\forall i \in \{1, \ldots, n\}$.

In this model, a complete seal is formed between $C$ and a target object parameterized by 3D mesh $M$ if and only if each of the perimeter springs of $C$ lies entirely on the surface of $M$. Given a target mesh $M$ with a target grasp $u = (p, v)$ for the gripper, we choose an initial configuration of $C$ such that $C$ is undeformed and the approach line $(p, v)$ passes through $a$ and is orthogonal to the base of $C$. Then, we make the following assumptions to determine a final static contact configuration of $C$ that forms a complete seal against $M$ (see Fig. 1):

- **The perimeter springs** of $C$ must not deviate from the original undeformed regular $n$-gon when projected onto a plane orthogonal to $v$. This means that their locations can be computed by projecting them along $v$ from their original locations onto the surface of $M$.
- **The apex**, $a$, of $C$ must lie on the approach line $(p, v)$ and, given the locations of $C$’s base vertices, must also lie at a location that keeps the average distance along $v$ between $a$ and the perimeter vertices equal to $h$.

See the supplemental file for additional details.

Given this configuration, we check its feasibility to determine if a complete seal is actually achievable. The configuration is feasible if:

- The cone faces of $C$ cannot collide with $M$ during approach or in the contact configuration.
- The surface of $M$ has no holes within the contact ring traced out by $C$’s perimeter springs.
- The energy required in each spring to maintain the contact configuration of $C$ is below a threshold.

We threshold the energy in individual springs rather than the total energy for $C$ because air gaps are usually caused by local geometry – for example, a small groove in the mesh’s surface would require a significant amount of deformation energy from small sections of the cup, but the overall deformation energy could still be low if the rest of the mesh is planar.

### B. Wrench Space Analysis

To determine whether or not the suction cup can resist external wrenches such as gravity through contact, we analyze the set of wrenches that the suction cup can apply.

1) **Wrench Resistance:** The object wrench set for a grasp using a contact model with $m$ basis wrenches is $\Lambda = \{w \in \mathbb{R}^6 \mid w = G \alpha \text{ for some } \alpha \in \mathcal{F}\}$, where $G \in \mathbb{R}^{6 \times m}$ is a set of $m$ basis wrenches in the object coordinate frame, and $\mathcal{F} \subseteq \mathbb{R}^m$ is a set of constraints on contact wrench magnitudes [25].

**Definition 2:** A grasp $u$ achieves wrench resistance with respect to $w$ if $-w \in \Lambda$. We encode wrench resistance as a binary variable $W$ such that $W = 0$ if $u$ resists $w$ and $W = 0$ otherwise.

2) **Suction Contact Model:** Many suction contact models acknowledge normal forces, vacuum forces, tangential friction, and torsional friction [2], [17], [24], [31] similar to a point contact with friction or soft finger model [25]. However, under this model, a single suction cup cannot resist torques about axes in the contact tangent plane, implying that any torque about such axes would cause the suction cup to drop an object (see the supplementary material for a detailed proof). This defies our intuition since empirical evidence suggests that a single point of suction can robustly transport objects [7], [11].

We hypothesize that these torques are resisted through an asymmetric pressure distribution on the ring of contact between the suction cup and object, which occurs due to passive elastic restoring forces in the material. Fig. 2 illustrates the suction ring contact model. The grasp map $G$ is defined by the following basis wrenches:

1) **Actuated Normal Force** ($f_z$): The force that the suction cup material applies to the object along the $z$ axis.
2) **Vacuum Force** ($V$): The magnitude of the constant force pulling the object into the suction cup coming from the air pressure differential.
3) **Frictional Force** ($f_f = (f_x, f_y)$): The force in the contact tangent plane due to the normal force between the suction cup and object, $f_f = f_z + V$.
4) **Torsional Friction** ($\tau_z$): The torque resulting from frictional forces in the ring of contact.
5) **Elastic Restoring Torque** ($\tau_e = (\tau_x, \tau_y)$): The torque about axes in the contact tangent plane resulting from elastic restoring forces in the suction cup pushing on the object along the boundary of the contact ring.

The magnitudes of the contact wrenches are constrained due to (a) the friction limit surface [14], (b) limits on the elastic behavior of the suction cup material, and (c) limits on the vacuum force. In the suction ring contact model, $\mathcal{F}$ is defined by a set of linear constraints for efficient computation.
of wrench resistance:

\[\text{Friction: } \sqrt{3}|f_x| \leq \mu f_N \quad \sqrt{3}|f_y| \leq \mu f_N \quad \sqrt{3}|\tau_z| \leq r\mu f_N\]

\[\text{Material: } \sqrt{2}|\tau_x| \leq \pi r\kappa \quad \sqrt{2}|\tau_y| \leq \pi r\kappa\]

\[\text{Suction: } f_s \geq -V\]

Here \(\mu\) is the friction coefficient, \(r\) is the radius of the contact ring, and \(\kappa\) is a material-dependent constant. These constraints define a subset of the friction limit ellipsoid and cone of admissible elastic torques under a linear pressure distribution about the ring of the cup. Furthermore, we can compute wrench resistance using quadratic programming due to the linearity of the constraints. See the supplemental file for a detailed derivation and proof.

C. Robust Wrench Resistance

We evaluate the robustness of candidate suction grasps by evaluating seal formation and wrench resistance over distributions on object pose, grasp pose, and disturbing wrenches:

Definition 3: The robust wrench resistance metric for \(u\) and \(x\) is \(p(u,x) = q(W | u, x)\) where \(q\) is a distribution over object poses, grasp poses, and disturbing wrenches.

In practice, we evaluate robust wrench resistance by taking \(M\) samples, evaluating wrench resistance for each, and computing the sample mean: \(\sum_{j=1}^{M} W_i\).

V. Dex-Net 3.0 Dataset

To learn to predict grasp robustness based on noisy point clouds, we generate the Dex-Net 3.0 training dataset of point clouds, grasps, and grasp success labels by sampling tuples \((S_i, u_i, y_i)\) from a joint distribution \(p(S, u, x, y)\) that is composed of distributions on:

- **Grasp Candidates**: \(p(u|x)\): A prior constraining grasp candidates to target points on the object surface.
- **Grasp Successes**: \(p(S | u, x)\): A stochastic model of wrench resistance for the gravity wrench.
- **Observations**: \(p(y | x)\): A sensor noise model.

To sample from the model, we first sample a latent state by selecting an object at random from a database of 3D CAD models and sampling a friction coefficient, planar pose of the object, and camera height above the table. We generate a set of grasp candidates for the object model by sampling points and normals uniformly at random from the surface of the object mesh. We then evaluate robust wrench resistance \(\rho\) as described in Section IV-C and convert to a binary label \(S = 1(\rho > \epsilon)\) for a threshold \(\epsilon = 0.2\). Finally, we apply a point cloud of the scene using rendering and a model of image noise [23]. The grasp success labels are associated with pixel locations in images through perspective projection [10]. Fig. 3 illustrates a subset of the Dex-Net 3.0 object and grasp dataset. Our pipeline for computing grasp robustness and generating training datapoints is illustrated in Fig. 4. Details on the distributions can be found in the supplemental file.

VI. LEARNING A DEEP ROBUST GRASPING POLICY

We use the Dex-Net 3.0 dataset to train a GQ-CNN that takes as input a single-view point cloud of an object resting on the table and a candidate suction grasp defined by a target 3D point and approach direction, and outputs the robustness, or estimated probability of success for the grasp on the visible object.

Our GQ-CNN architecture is identical to Dex-Net 2.0 [22] except that we modify the pose input stream to include the angle between the approach direction and the table normal and change the pcl layer from size 16 to 64. The point cloud stream takes a depth image centered on the target point and rotated to align the middle column of pixels with the approach orientation similar to a spatial transforming layer [12]. The end-effector depth from the camera and orientation are input to a fully connected layer in a separate layer [12]. The end-effector depth from the camera and orientation are input to a fully connected layer in a separate layer [12]. The end-effector depth from the camera and orientation are input to a fully connected layer in a separate layer [12]. The end-effector depth from the camera and orientation are input to a fully connected layer in a separate layer [12]. The end-effector depth from the camera and orientation are input to a fully connected layer in a separate layer [12].
We ran experiments to characterize the precision of robust wrench resistance when object shape and pose are known and the precision of our deep robust grasping policy for planning grasps from point clouds for three object classes.

A. Object Classes

We created a dataset of 55 rigid and non-porous objects including tools, groceries, office supplies, toys, and 3D printed industrial parts. We separated objects into three categories, illustrated in Fig. 6:

1) Basic: Prismatic solids (e.g. rectangular prisms, cylinders). Includes 25 objects.
2) Typical: Common objects with varied geometry and many accessible, approximately planar surfaces. Includes 25 objects.
3) Adversarial: 3D-printed objects with complex geometry (e.g. curved or narrow surfaces) that are difficult to access. Includes 5 objects.

For object details, see http://bit.ly/2xMcx3x.

B. Experimental Protocol

We ran experiments with an ABB YuMi with a Primesense Carmine 1.09 and a suction system with a 15mm silicone single-bellow suction cup and a VM5-NC vacuum generator with a payload of approximately 0.9kg. The experimental workspace is illustrated in the left panel of Fig. 6. In each experiment, the operator iteratively presented a target object to the robot and the robot planned and executed a suction grasp on the object. On each trial, the operator labeled successes based on whether or not the robot was able to lift and transport the object to the side of the workspace. For each method, we measured:

1) Average Precision (AP). The area under the precision-recall curve, which measures precision over possible thresholds on the probability of success predicted by
the policy. This is useful for industrial applications where a robot may take an alternative action (e.g. asking for help) if the planned grasp is predicted to fail.

2) **Success Rate.** The fraction of all grasps that were successful.

All experiments ran on a Desktop running Ubuntu 14.04 with a 2.7 GHz Intel Core i5-6400 Quad-Core CPU and an NVIDIA GeForce 980 GPU.

**C. Performance on Known Objects**

To assess performance of our robustness metric independently of the perception system, we evaluated whether or not the metric was predictive of suction grasp success when object shape and pose were known using the 3D printed Adversarial objects. The robot was presented one of the five Adversarial objects in a known stable pose, selected from the top three most probable stable poses. We hand-aligned the object to a template image generated by rendering the object to a known pose on the table. Then, we indexed a database of grasps precomputed on 3D models of the objects and executed the grasp with the highest metric value for five trials. In total, there were 75 trials per experiment.

We compared the following metrics:

1) **Planarity-Centroid (PC3D).** The inverse distance to the object centroid for sufficiently planar patches on the 3D object surface.

2) **Spring Stretch (SS).** The maximum stretch among virtual springs in the suction contact model.

3) **Wrench Resistance (WR).**

4) **Robust Wrench Resistance (RWR).**

The RWR metric performed best with 99% AP compared to 93% AP for WR, 89% AP for SS, and 88% for PC3D.

**D. Performance on Novel Objects**

We also evaluated the performance of GQ-CNNs trained on Dex-Net 3.0 for planning suction target points from a single-view point cloud. In each experiment, the robot was presented one object from either the Basic, Typical, or Adversarial classes in a pose randomized by shaking the object in a box and placing it on the table. The object was imaged with a depth sensor and segmented using 3D bounds on the workspace. Then, the grasping policy executed the most robust grasp according to a success metric. In this experiment the human operators were blinded from the method they were evaluating to remove bias in human labels.

We compared policies that optimized the following metrics:

1) **Planarity.** The inverse sum of squared errors from an approach plane for points within a disc with radius equal to that of the suction cup.

2) **Centroid.** The inverse distance to the object centroid.

3) **Planarity-Centroid.** The inverse distance to the centroid for planar patches on the 3D object surface.

4) **GQ-CNN (ADV).** A GQ-CNN trained on synthetic data from the Adversarial objects (to assess the ability of the model to fit complex objects).

5) **GQ-CNN (DN3).** A GQ-CNN trained on synthetic data from 3DNet [35], KIT [16], and the Adversarial objects.

Table I details performance on the Basic, Typical, and Adversarial objects. We see that the Dex-Net 3.0 policy has the highest AP across the Basic and Typical classes. The Dex-Net 3.0 policy took an average of approximately 3 seconds to plan each grasp.

**E. Failure Modes**

The mode common failure mode was attempting to form a seal on surfaces with small variations such as ridges and indentations that prevent a seal formation. We believe this is due to the limited resolution of the depth sensor, as our seal formation model is able to detect the inability to form a seal on such surfaces. The GQ-CNN-based policy also tends to fail on objects with small protrusions such as wall hooks.

**VIII. DISCUSSION AND FUTURE WORK**

We presented a novel compliant model of suction contact and generated the Dex-Net 3.0 dataset from the model to train a deep CNN to predict grasp success from point clouds. Our experiments suggest that our suction contact model has high precision in predicting grasp success in physical trials.

In future work we plan to study the effect of the prior object dataset on system performance. We are interested in synthetic object dataset augmentation using different scales, mass distributions, and shapes. Furthermore, we plan to evaluate performance with higher resolution depth sensors. Finally, we are also interested in using the suction grasping policy as a primitive for bin picking, where a high-level policy decides between using parallel jaws or suction based on the predicted probability of success.

**REFERENCES**

TABLE I: Performance of image-based grasping policies for 125 trials each on the Basic and Typical datasets and 100 trials each on the Adversarial datasets. We see that the GQ-CNN trained on Dex-Net 3.0 has the highest average precision on the Basic and Typical objects but has lower precision on the adversarial objects, which are very different than common objects in the training dataset. A GQ-CNN trained on the Adversarial dataset significantly outperforms all methods on these objects, suggesting that our model is able to capture complex geometries when the training dataset contains a large proportion of such objects.
